Multimodal Study of Default-Mode Network Integrity in Disorders of Consciousness

Cristina Rosazza, PhD,1,2 Adrian Andronache, PhD,1 Davide Sattin, PsyD,3 Maria Grazia Bruzzone, MD,1 Giorgio Marotta, MD,4 Anna Nigri, MSc,1 Stefania Ferraro, MSc,1 Davide Rossi Sebastiano, MD,5 Luca Porcu,6 Anna Bersano, MD,7 Riccardo Benti, MD,4 Matilde Leonardi, MD,3 Ludovico D’Incerti, MD,1 and Ludovico Minati, PhD, CEng, CPhys, CSci,2 on behalf of the Coma Research Center, Besta Institute

Objective: Understanding residual brain function in disorders of consciousness poses extraordinary challenges, and imaging examinations are needed to complement clinical assessment. The default-mode network (DMN) is known to be dysfunctional, although correlation with level of consciousness remains controversial. We investigated DMN activity with resting-state functional magnetic resonance imaging (rs-fMRI), alongside its structural and metabolic integrity, aiming to elucidate the corresponding associations with clinical assessment.

Methods: We enrolled 119 consecutive patients: 72 in a vegetative state/unresponsive wakefulness state (VS/UWS), 36 in a minimally conscious state (MCS), and 11 with severe disability. All underwent structural MRI and rs-fMRI, and a subset also underwent 18F-fluorodeoxyglucose positron emission tomography (FDG-PET). Data were analyzed with manual and automatic approaches, in relation to diagnosis and clinical score.

Results: Excluding the quartile with largest head movement, DMN activity was decreased in VS/UWS compared to MCS, and correlated with clinical score. Independent-component and seed-based analyses provided similar results, although the latter and their combination were most informative. Structural MRI and FDG-PET were less sensitive to head movement and had better diagnostic accuracy than rs-fMRI only when all cases were included. rs-fMRI indicated relatively preserved DMN activity in a small subset of VS/UWS patients, 2 of whom evolved to MCS. The integrity of the left hemisphere appears to be predictive of a better clinical status.

Interpretation: rs-fMRI of the DMN is sensitive to clinical severity. The effect is consistent across data analysis approaches, but heavily dependent on head movement. rs-fMRI could be informative in detecting residual DMN activity for those patients who remain relatively still during scanning and whose diagnosis is uncertain.

Diagnosis, prognosis, and planning of rehabilitation in patients with DOC remain challenging.1 The clinical assessment of residual consciousness at the bedside is difficult particularly between VS/UWS and MCS, and there
remain difficulties in determining antemortem the location, type, and severity of central nervous system pathology causing DOC in single patients.2–6

Neuroimaging methods complement clinical diagnosis and neurophysiological investigations for assessing residual consciousness and cognitive function. Magnetic resonance imaging (MRI) is the preferred method to visualize the location and extent of damage to the cortex, midbrain, and upper brainstem. Depending on etiology, structural imaging shows heterogeneous lesion patterns including diffuse axonal injury, multifocal cortical contusions, and thalamic damage. The potential of structural MRI (sMRI) in the study of DOC has been less thoroughly investigated, although advanced MRI techniques such as diffusion tensor imaging (DTI) have been used to differentiate VS/UWS from MCS.7

Key advances in understanding DOC have come from 18F-fluorodeoxyglucose positron emission tomography (FDG-PET). FDG-PET studies in resting-state conditions demonstrated considerable decrease in brain metabolism in DOC, namely, medial and lateral frontoparietal associative cortices are the most hypometabolic areas in VS/UWS and have better preserved metabolism in MCS.2,8–10 Recent studies have confirmed that metabolic integrity can disentangle VS/UWS from MCS patients with good accuracy and predict clinical outcome.11,12

To extend PET findings, functional MRI has been applied in resting-state conditions and during active tasks. Resting-state functional MRI (rs-fMRI) reveals multiple cortical networks of synchronized activity. One of these networks is known as the default-mode network (DMN), which encompasses the precuneus, lateral parietal cortex, and mesial prefrontal cortex. It subserves large-scale integrative processes related to mind wandering, memory consolidation, and awareness.13–15

The DMN activity, plausibly alongside all other cortical networks, is absent in brain death and irreversible coma but can be partially preserved in VS/UWS.16–21 In MCS, the DMN is somewhat stronger than in VS/UWS, but severely impaired compared to healthy subjects.18,19,21 Recently, it has been shown that preservation

Etiology is reported as traumatic/vascular/anoxic (No.). Age, disease duration, and CRS-R scores are given as median (range). “75%” denotes the subgroup corresponding to exclusion of the quartile with largest head movement during resting-state functional magnetic resonance imaging scanning; “with PET” denotes the subgroup of patients for whom 18F-fluorodeoxyglucose-PET data were available.

CRS-R = Coma Recovery Scale–Revised; F = female; M = male; MCS = minimally conscious state; PET = positron emission tomography; SD = severe disability; VS/UWS = vegetative state/unresponsive wakefulness state.
of functional connectivity between frontal and parietal DMN regions is a significant marker for recovery from coma after 3 months.\(^2\)\(^2\)

Although in some domains rs-fMRI is capable of attaining rather high diagnostic accuracy levels,\(^2\)\(^3\)\(^–\)\(^2\)\(^5\) its clinical value in DOC remains unclear. rs-fMRI is highly sensitive to head movement, and DMN detection critically depends on data filtering choices.\(^2\)\(^6\) Yet, although active techniques such as mental imagery have very high specificity for conscious awareness, rs-fMRI may deliver increased sensitivity to residual brain activity given that it does not require active patient compliance. To date, only few studies have reported correlation with the clinical signs of consciousness as measured by the Coma Recovery Scale–Revised (CRS-R) scale,\(^1\)\(^8\)\(^,\)\(^1\)\(^9\) and to our knowledge no study has detected statistically significant differences in DMN activity between VS/UWS and MCS at the group level. In addition, these findings relate to relatively small patient samples (approximately 14–25 cases), with few exceptions (eg, Demertzi et al,\(^2\)\(^7\) with 53 DOC patients), and generally the patients included were on average in subacute phase.\(^1\)\(^8\)–\(^2\)\(^1\)\(^2\),\(^2\)\(^7\)

Here, we investigated the association between DMN integrity and consciousness level represented as diagnosis (VS/UWS, MCS, or SD) and clinical assessment (CRS-R scores) in 119 DOC patients with disease duration on average >2 years. An element of novelty is that DMN integrity was assessed multimodally: (1) functionally, based on independent component analysis (ICA) and seed-based analysis (SBA) of rs-fMRI, rated both automatically and visually by expert operators; (2) anatomically, based on visual ratings of anatomical damage in the DMN regions, as visualized by conventional MRI scans; and (3) metabolically, based on average FDG uptake measures in the DMN regions.

**Subjects and Methods**

**Participants**

Adult DOC patients, who underwent a 1-week program of multidisciplinary assessment during 2011–2013 at the Coma Research Center (CRC) of the Fondazione IRCCS Istituto Neurologico “Carlo Besta”, Milan, Italy, were enrolled prospectively. The study was approved by the institutional ethics committee of the CRC. rs-fMRI was performed in 119 of the 153 consecutive DOC patients admitted during the study period; data from all these patients were included in the present analyses. A subgroup of 85 patients also underwent FDG-PET at the Fondazione IRCCS Ca’ Granda Ospedale Maggiore Policlinico, Milan, Italy. Demographic and clinical characteristics are reported in the Table. According to the Aspen criteria,\(^2\)\(^8\) 72 patients were clinically classified as VS/UWS, 36 as MCS, and 11 as SD. Etiology included 42 anoxic brain injury, 41 vascular brain injury, and 36 traumatic brain injury; median disease duration was 26 months (range = 2–252, >12 months for 92 cases); and median age was 52 years (range = 19–83).

Patients were assessed with the Italian version of the CRS-R\(^2\)\(^9\),\(^3\)\(^0\); each patient was independently assessed 4 times by experienced raters, and the best response was used to establish the final value.

A group of 33 healthy participants (median age = 39 years, range = 17–66) with no history of neurological deficits was recruited as controls.\(^2\)\(^6\) Written informed consent was obtained from patient guardians and healthy participants.

**MRI Data Acquisition**

Scanning was performed on a 3T scanner with a 32-channel head coil (Achieva TX; Philips Healthcare, Best, the Netherlands). The following structural images were acquired: volumetric magnetization-prepared rapid acquisition gradient echo (MP-RAGE), sagittal T\(_1\)-weighted turbo spin echo (TSE) inversion recovery (IR), axial T\(_2\)-weighted TSE, and coronal fluid-attenuated inversion recovery (FLAIR); except for the volumetric series, in-plane resolution was ~0.9mm with 4mm slice thickness. For rs-fMRI, 200 gradient-echo–echo-planar image volumes were acquired with repetition time = 2.8 seconds, echo time = 30 milliseconds, \(\pi = 70\)°, 2.5mm isotropic voxel size, 90 × 95 matrix size, 50 slices with 10% gap, and ascending order. Sequence duration was ~9.5 minutes. When patient posture allowed, the head was restrained using foam pillows, and a knee wedge was positioned to minimize spine movement and discomfort. Sedation was never performed.

**rs-fMRI Data Preprocessing**

A pre-processing pipeline including standard modules implemented in SPM8 (Wellcome Trust Centre for Neuroimaging, London, UK) and custom code developed in MATLAB 7 (MathWorks, Natick, MA) was used.\(^2\)\(^6\) It consisted of spatial realignment, slice-timing correction, and normalization to 2mm Montreal Neurological Institute space by coregistration to the individual T1 structural scan and subsequent segmentation and normalization. Manual censoring of movement-affected segments was performed, leading to rejection of 1 or more volumes in 42 patients (median number of rejected volumes = 38). Movement-related variance was removed by multilinear regression, with 3rd-order polynomial detrending and 0.1Hz low-pass filtering. Residual global signal fluctuations were regressed out, and 8mm smoothing was applied.

**ICA**

ICA was performed independently for each participant, using the group ICA of fMRI toolbox (GIFT; MIALab, University of New Mexico, Albuquerque, NM) and a fixed number of 20 components,\(^3\)\(^1\) which were saved in z-rescaled format. To enable automatic rating of the DMN, the following steps were applied: (1) a DMN mask was derived thresholding a statistical group map (\(\tau > 5\)) computed over the control participants, selecting the 3 posterior nodes (precuneus with extension to posterior cingulate cortex [PCC], and lateral parietal cortex [LPC]), whereas the medial frontal cortex (MFC) node was...
excluded, as its activity was weaker in our controls and generally in DOC patients, and thus rendered DMN identification less reliable; (2) for each participant and component (thresholded at $z > 2$), the proportion of suprathreshold voxels was calculated separately for the left and right PCC and LPC and averaged, then the percentage of suprathreshold voxels outside the DMN mask was subtracted from each individual component, and the difference map was thresholded at $z > 0.20$; and (3) in the case there were no suprathreshold components, the DMN map was zero-filled. After DMN identification using the above procedure, to quantify PCC, LPC and MFC activity (MFC included for measurement, although not for the DMN identification), the proportion of $z > 2$ voxels was measured separately for each region.32

SBA
SBA was independently performed for 6 seeds, located in left and right PCC, LPC and MFC. These were defined based on a pre-existing DMN group map intersected with corresponding Automated Anatomical Labeling atlas cortical regions ($67, 68, 65, 66, 23, and 24$). The mean time-course of each seed was entered into a correlation analysis, and corresponding statistical maps were thresholded at $t > 4$. For SBA, no automatic measurements were performed, given that in many cases very strong and diffuse, unspecific correlation was observed; hence, for this technique expert inspection of the maps was essential to determine whether a DMN-related topographical pattern was present.

rs-fMRI Visual Ratings
For each patient, rating was performed by 2 expert investigators blind to all patient data. The component(s) visualizing DMN activity were manually chosen from the 20 extracted by ICA. Because DMN activity could split over 2 (left and right) ICA components, up to 2 components could be chosen. Overall, 66% of patients had no identifiable DMN, 25% had DMN in 1 ICA component, and 9% had DMN in 2 ICA components. During selection of the ICA component(s) showing DMN activity, SBA maps were also visualized to increase operator confidence. The DMN was then rated in 3 different manners during separate sessions. First, the ICA map was considered alone and a score of 0 or 1 was assigned to each node; for this analysis, all scores were clamped to zero if no DMN component could be identified in the previous step. Second, only the 6 SBA maps were considered and a score of 0, 0.5, or 1 was assigned to each node; for this analysis, 0.5 was assigned if correlated activity was observed for a given node on 1 map only, and 1 was assigned if it was visible on 2 or more maps. Third, SBA and ICA were considered together; for this analysis, a score of 0.5 was assigned to each node if correlated activity beyond the PCC was visible on ICA and SBA maps. Across all sessions, the operators searched for the presence of clear, well-defined clusters of correlated activity resembling the known DMN pattern established in controls; in particular, large clusters of correlated activity, without anatomical specificity, were disregarded.

Ratings were given independently by the 2 raters, then reconsidered in cases of disagreement; they were thereafter summed across nodes and averaged across the raters, yielding for each patient 3 overall scores: ICA alone, SBA alone, and ICA+SBA together. Inter-rater agreement was 92% for DMN identification, and $\rho = 0.80$ for ICA, $\rho = 0.94$ for SBA, and $\rho = 0.90$ for ICA+SBA.

sMRI Visual Rating
Two expert neuroradiologists blind to all patient data rated the severity of gross anatomical and signal abnormality corresponding to the expected DMN nodes location according to the following scale: 0 (severely damaged, ie, parenchyma obliterated and/or intense, pervasive hyperintensity), 1 (recognizable but distorted morphology and/or severe signal abnormality), 2 (moderate anatomical damage and/or signal abnormality), 3 (mild anatomical damage and/or signal abnormality), and 4 (normal-appearing). Ratings were given independently by the 2 raters, and reconsidered in cases of large disagreement; the scores were then averaged together. Inter-rater agreement was $\rho = 0.88$.

FDG-PET Data Acquisition and Analysis
Scanning was performed on a Biograph Truepoint 64 PET/CT scanner (Siemens, Erlangen, Germany). Patients rested in a quiet, dimly lit room during FDG uptake ($140 \pm 30$MBq) for at least 40 minutes. Each acquisition included a transmission scan followed by a 3-dimensional static emission for 15 minutes. PET sections were reconstructed using iterative ordered-subset expectation maximization (6 iterations, 8 subsets), corrected for scatter and attenuation, then reconstructed to in-plane voxel size = 1.3mm, thickness = 3.0mm.

Standardized uptake value (SUV) maps were derived as $\text{SUV} = \frac{\text{AC}}{(\text{FDGdose}/\text{BW})}$, where AC represents activity concentration in kilobecquerels per milliliter in a given voxel, FDGdose is the injected radiotracer dose in megabecquerels corrected for residual activity in the syringe, and BW is the body weight in kilograms. SUV maps were thereafter coregistered using SPM12 to individual volumetric T1 series, which were segmented to generate the normalization deformation field to be applied to the coregistered FDG-PET scan. The normalized PET images were finally smoothed with a 10mm isotropic Gaussian filter. Using the DMN mask derived from the controls as described above for ICA analysis, the average SUV values for PCC, LPC and MFC were computed.

Voxelwise Group Map Analyses
Group-level analyses were performed using Statistical NonParametric Mapping (http://warwick.ac.uk/snpm), which implements a nonparametric multiple comparisons procedure based on randomization/permutation. This was chosen as data were not normally distributed due to the presence of zero-filled DMN maps. We conducted separate analyses for ICA, SBA (combining the maps from the left and right PCC via voxelwise maximum), and FDG-PET. For each technique, we performed (1) a correlation analysis with respect to diagnosis encoded as
0: VS/UWS, 1: MCS, and 2: SD (after Vanhaudenhuyse et al\textsuperscript{39}); (2) a correlation analysis with respect to the CRS-R score; and (3) a group comparison between VS/UWS and MCS.

**Statistical Analyses**

As indicated in the Table, statistical analyses were performed on 4 subsamples: (1) all patients (n = 119), (2) the 75% of patients with smallest median frame-to-frame displacement as obtained from rigid-body frame realignment (n = 89), (3) all patients who underwent FDG-PET (n = 85), and (4) patients from the second subsample who also underwent FDG-PET (n = 62). This subdivision was necessary due to the uneven number of patients for whom MRI and PET data were available, and to highlight rs-fMRI sensitivity to head movement; the 75% threshold was determined a priori in preliminary analyses, blinded to the present data. As indicated below, this threshold corresponds to median framewise displacement of about 0.3mm, which is moderately conservative according to the criteria described in Power et al.\textsuperscript{36,37} This allows us to reject those cases that in other studies would have likely been rejected outright due to excessive movement.

We considered the “entire DMN” combining scores (ie, arithmetic averaging) of the MFC, PCC and LPC and separately, the “posterior DMN” combining PCC and LPC, scores, as correlated activity is weaker in MFC compared to the posterior nodes.

We assessed the statistical association of the imaging modalities (sMRI, rs-fMRI, and FDG-PET) with respect to the VS/UWS and MCS diagnosis by means of a logistic regression model. First, univariate logistic models were performed for each predictor, that is, imaging modality (p < 0.05), then only the significant variables were considered for the development of a multivariate logistic regression model. A backward selection procedure (p < 0.05) starting with the inclusion of all predictors was used to eliminate nonsignificant predictors and to identify a final parsimonious multivariate logistic model which accomplishes the desired level of explanation with as few predictors as possible. From each final multivariate model, the maximum likelihood estimator provided a score for each patient that was used to estimate the area under a receiver operating characteristics curve (AUC). AUC was used as a measure of diagnostic discrimination for univariate and multivariate logistic models; the equality of correlated AUCs were compared using Stata’s `roccomp` command (v12; StataCorp, College Station, TX).\textsuperscript{38}

Furthermore, correlations between the imaging scores and the CRS-R score and between the level of structural damage (sMRI) and the functional modalities (rs-fMRI, FDG-PET) were assessed with nonparametric Spearman ρ (p < 0.05). To estimate 95% confidence intervals, Fisher \( z \)-transformation and Fisher bias correction were used. To assess the presence of heterogeneity with respect to etiology (traumatic, vascular, anoxic) and lateralization of DMN nodes (PCC, LPC, MFC), a Q test was used (p < 0.05); to quantify the degree of heterogeneity, the \( F^2 \) index was used.\textsuperscript{38}

**Results**

**Group Analyses**

As shown in Supplementary Table 1, over the whole sample (100% of ALL, n = 119), sMRI visual ratings of anatomical damage predicted VS/UWS from MCS and correlated moderately with CRS-R scores (up to \( p = 0.35 \)). Conversely, none of the rs-fMRI measures was sensitive to diagnosis, and correlations with CRS-R scores were weak (p < 0.2). Excluding the quartile with largest head movement (75% of ALL, n = 89), significant prediction between VS/UWS and MCS appeared for almost all rs-fMRI measures, with moderate correlation with the CRS-R score (up to \( p = 0.35 \), see Supplementary Table 1). Of the 4 rs-fMRI measures considered, visual ratings of SBA and ICA+SBA yielded the strongest results, although all rs-fMRI measures were highly correlated (p < 0.85). Considering the subsample of patients who underwent FDG-PET (100% of ALL with PET, n = 85), SUV values predicted VS/UWS from MCS, and led to the highest correlation with the CRS-R score (p = 0.41); in this subsample, sMRI ratings maintained similar performance to the above, but rs-fMRI measures were poorly informative. Excluding the quartile with largest head movement and considering only the subsample of patients who underwent FDG-PET (75% of ALL with PET, n = 62), sMRI and FDG-PET measures slightly diminished. Even if considering all DMN nodes or only posterior regions led to similar results, correlation and significance scores tended to be stronger for the posterior nodes.

As visualized in Figure 1, voxelwise statistical analyses suggested that ICA was superior to SBA, showing an effect of diagnosis, and correlation with the CRS-R scores was more clearly localized to the DMN nodes. This result seems at odds with SBA visual ratings, which yielded significant results (see Supplementary Table 1), possibly for 2 reasons: visual ratings are guided by expert heuristics, whereas voxelwise statistics may be more vulnerable to localization variability; and SBA visual ratings were performed considering maps from all 6 seeds, whereas voxelwise group maps were generated considering only the precuneus as seed. As regards FDG-PET, voxelwise analyses of SUV maps delineated a broader set of regions, which encompass the posterior DMN nodes; whereas correlation with the CRS-R yielded a clear and broader effect, comparison of MCS versus VS/UWS led to a more constrained difference.

Figure 2 shows the diagnostic accuracy of each modality, represented in its optimal conditions, following the results reported in Supplementary Table 2, namely: (1) sMRI and FDG-PET are relatively insensitive to head...
movement, therefore they were assessed on all available cases; (2) for sMRI and FDG-PET, results are consistently stronger when only the posterior nodes are considered, therefore the posterior DMN was considered for these techniques; and (3) for rs-fMRI, the visual rating of ICA+SBA was chosen as it was the only predictor retained by multivariate logistic regression with backward prediction selection including all 4 rs-fMRI measures. For rs-fMRI, the entire DMN was considered because the frontal node was clearly involved in the group analyses (see Fig 1), although the results were similar for the entire DMN and the posterior DMN. Results show that, although AUCs were modest, FDG-PET led to the best classification accuracy between VS/UWS and MCS patients (AUC = 0.75), followed by sMRI (AUC = 0.72) and by rs-fMRI (AUC = 0.65). Correlations with CRS-R were moderate (0.31 < ρ < 0.41) and followed a similar pattern. All modalities revealed significant differences between VS/UWS and MCS.

Consideration of the logistic regressions and AUCs for separating VS/UWS and MCS patients (see Supplementary Table 2) revealed the following. First, Over the entire population (100% of ALL, n = 119), sMRI was significantly superior to rs-fMRI. Second, Excluding the quartile with largest head movement (75% of ALL, n = 89), their performance was similar. Third, Considering all patients who underwent FDG-PET (100% of ALL with PET, n = 85), sMRI and FDG-PET had similar performance and were clearly superior to rs-fMRI. In multivariate logistic regression, sMRI and FDG-PET were retained in the model, but rs-fMRI was eliminated; the performance of the multivariate model was
comparable to that of the single predictors (see AUCs). Four, Excluding the quartile with largest head movement and considering only the subsample of patients who underwent FDG-PET (75% of ALL with PET, \(n = 62\)), sMRI and rs-fMRI provided similar performance, and FDG-PET was slightly superior to both. In multivariate logistic regression, rs-fMRI and FDG-PET were retained in the model, but sMRI was eliminated; the performance of the multivariate model was comparable to that of the single predictors (see AUCs).

**Effect of Head Movement**

Supplementary Table 3 shows the proportion of patients in each group (VS/UWS, MCS, and SD) for whom DMN activity was detected, empirically defined as a score \(\geq 1\) on visual assessment of ICA+SBA, corresponding to detection of correlated activity between at least 2 DMN nodes. In the entire sample, head movement was largest for the MCS group, and rejection of the top quartile or half with largest head movement had the highest impact on this population (DMN detection ratio increased from 36% to 83%). By contrast, for SD patients the DMN was always detected, and for VS/UWS patients the detection ratio remained relatively stable.

For comparison, head movement was also calculated according to the well-accepted formula described in Power et al.,\(^{37}\) which includes rotations assuming a mean distance of 50mm between cerebral cortex and head center. Across all patients, this measure and the simple median displacement here considered for excluding high-movement cases were almost perfectly correlated (\(\rho > 0.99\)). The 75th percentile chosen as a threshold corresponded to a median framewise displacement of about 0.3mm, which is moderately conservative according to the criteria described in Power et al.\(^{37}\)
**Lateralization**

Following the asymmetry visible in Figure 1, we conducted additional analyses separately for the left and right hemispheres, aiming to ascertain possible lateralization of predictability of VS/UWS versus MCS (Supplementary Table 4). Overall, left hemispheric integrity was more strongly predictive of clinical status. Specifically, for sMRI and FDG-PET, univariate logistic regressions indicated that left and right hemispheres were both predictive, but multivariate logistic regression retained only the left. For rs-fMRI, the visual rating of ICA+SBA only provided separate hemispheric scores for the LPC, and only the left side was significantly predictive. We thus also considered automated ICA rating (proportion of suprathreshold voxels across MFC, PCC, and LPC) separately for the 2 hemispheres; here too, only the left side provided significant results.

As regards the single DMN regions, for sMRI and rs-fMRI, the AUCs for separating VS/UWS from MCS were generally left-lateralized among the PCC and LPC considered separately and the overall DMN, but lower for the MFC. For FDG-PET, lateralization in the separate DMN regions was overall less evident.

**Effect of Etiology**

Despite limited numerosity for some patient subsamples, we calculated separate AUC values for the 3 etiology groups (traumatic, vascular, anoxic). The $Q$ test and $F^2$ index did not reveal significant heterogeneity, indicating that the modalities had comparable diagnostic power irrespective of etiology. Nevertheless, for sMRI and rs-fMRI, the AUC was consistently highest for anoxic, followed by traumatic, and then by vascular etiology, across the 4 subsamples (Supplementary Table 5).

As regards the relationship between structural damage (sMRI) and results of rs-fMRI, the correspondence was strongest for anoxic etiology closely followed by traumatic etiology, and considerably weaker for vascular etiology; for FDG-PET, the correspondence with sMRI was also strongest for anoxic etiology, but here a graded effect was observed, with weaker correlation for vascular followed by traumatic etiology (Supplementary Table 6).

Clinical data as well as automatic and rating data performed on sMRI, rs-fMRI, and FDG-PET are reported in Supplementary Table 7.

**Two Anecdotal Cases**

Despite the above limitations, rs-fMRI may provide important additional information complementing the other modalities for some cases. Among patients clinically diagnosed to be in VS/UWS, 7 of 72 had a score $\geq 2$ for ICA+SBA visual rating, indicating high DMN preservation. Of these, 2 are described in detail to exemplify cases where the other techniques do not provide conclusive results, but the presence of a near normal-appearing DMN could indicate residual brain activity, motivating enhanced rehabilitation efforts. As limited follow-up data are available, this is only reported as anecdotal evidence. Of the remaining patients, 4 had remained stable and 1 had slightly deteriorated 2 years after scanning.

Case 1 (55-year-old woman, alias VS/UWS_24 in Supplementary Table 7) suffered a ruptured aneurysm, had a disease duration of 23 months, and had a CRS-R score of 6. Severe frontoparietal infarction, superficial siderosis, and left-sided atrophy were evident on MRI. FDG-PET identified a markedly asymmetrical pattern, with severe left hemisphere hypometabolism and relative right hemisphere preservation. Electroencephalogram (EEG) was markedly asymmetric, with slowed and reduced amplitude activity on the left and predominant theta activity on the right, and auditory cognitive evoked potentials (auditory P300; auditory mismatch negativity [MMN]) were present. rs-fMRI revealed a clear pattern of correlated activity in DMN nodes. The integrity of functional connections among bilateral precuneus, MFC, and right LPC was concordantly confirmed by ICA and SBA; by contrast, synchronized activity in the left LPC was never detected, even when this area was considered as SBA seed. Two years after scanning, the CRS-R visual scale improved for presence of visual pursuit, and diagnosis was changed to MCS.

Case 2 (76-year-old man, alias VS/UWS_66 in Supplementary Table 7) suffered postsurgical brain hemorrhage, had a disease duration of 15 months, and had a CRS-R score of 6. Severe bilateral frontotopical atrophy, white matter hyperintensity, and superficial siderosis were evident on MRI. FDG-PET identified severe hypometabolism in the right frontal area and moderate left frontoparietal hypometabolism. Symmetric EEG with slowed and reduced amplitude activity and localized interictal epileptiform activity was present, and auditory cognitive evoked potentials (P300, MMN) were absent. rs-fMRI revealed correlated activity in all posterior DMN regions, and this pattern was more evident with SBA than ICA. As regards the medial frontal node, no correlated activity was detected; when considering this area as seed region, spurious clusters of correlated signal appeared in the fornix and ventricles, plausibly due to the non-neural physiological signal fluctuations often observed in these regions. In conjunction with treatment with amantadine, the patient improved for the presence of visual pursuit and was diagnosed as MCS for approximately 1 year.
Discussion

We investigated the integrity of DMN in relation to consciousness with rs-fMRI in the largest group of DOC patients studied so far, directly comparing rs-fMRI with sMRI and PET. We confirm a significant relationship between functional, anatomical, and metabolic integrity of the DMN and clinical status, and provide additional insight on the potential clinical contribution of each technique.

rs-fMRI Analyses and Their Sensitivity to Clinical Status

Our data show that DMN functional connectivity strength differentiates MCS from VS/UWS patients, correlating with the clinical status measured with CRS-R, in line with other studies. Excluding patients with largest head movement, all 4 rs-fMRI measures (auto ICA, visual ICA, visual SBA, visual ICA+SBA) indicated that greater correlated activity within the DMN was associated with higher consciousness level. Although SBA-ICA agreement is good overall, visual ratings of SBA alone and ICA+SBA together yielded the strongest statistical scores because considering multiple maps allowed more confident and reliable assessment. We therefore advise that, when possible, ICA and SBA should be combined or multiple SBA seeds should be considered. Notably, automatic and visual rating yielded similar results, confirming that implementing in clinical routine rs-fMRI based on expert visual assessment is acceptable, although automated rating can be less biased.

In our study, the DMN was identifiable in ~30% of VS/UWS cases and in ~59% of MCS cases, ranging from 36% to 83% depending on the number of patients excluded for head movement, and always recognizable in SD cases. However, attention was focused on VS/UWS to determine whether patients show residual functional activity and signs of consciousness. For cases where diagnostic classification is uncertain, evidence of synchronized activity between anatomically distant nodes could prompt more careful evaluation of the patient’s condition.

Limited Overall Diagnostic Accuracy with Potential Relevance for Some Individual Cases

The results of this study warn about the impact of movement during rs-fMRI. In the favorable scenario of low or no movement, rs-fMRI seems to have high sensitivity to DMN activity; however, a sizable proportion of cases, especially MCS patients, move during scanning (see Supplementary Table 3), curtailing the diagnostic potential of this technique. It is customary in studies in this area to focus on patients with acceptably low head movement, rejecting outright cases where acquisitions cannot be performed satisfactorily due to movement. Here, to accurately represent clinical reality, we chose to include all patients who could be scanned and a posteriori, blinded to the clinical data, we removed those most affected by movement. The overall diagnostic accuracy of rs-fMRI is below accepted thresholds for consideration as a biomarker ($AUC = 0.65$). Univariate and multivariate regression indicated that sMRI and rs-fMRI had comparable diagnostic accuracy, and that the latter did not provide additional information. Nevertheless, rs-fMRI could yield clinically impacting results for some individual cases in which the VS diagnosis is uncertain. In a minority of VS/UWS cases of our cohort, this network was clearly identifiable in spite of mediocre or inconclusive results from other modalities. In particular, 2 cases reported in Figure 3 emerged from VS in the months following scanning, suggesting that rs-fMRI evidence of preserved synchronized activity may have some prognostic value.

This view is supported by a recent study showing that the level of preservation of frontoparietal connectivity can predict the clinical outcome of comatose patients at 3 months. We hypothesize that rs-fMRI might be useful for detecting cases where additional diagnostics or increased rehabilitation efforts may be motivated in light of possible conversion to MCS. This question, however, can only be answered via a follow-up study. In our cohort of patients, evidence of association between DMN integrity and clinical recovery was limited to 2 anecdotal cases, and the recovery was quantitatively small, that is, evolution to MCS was only determined by the presence of visual pursuit. Here, only relatively small changes in clinical status could be expected, given the long average disease duration of this cohort. DMN integrity is neither a prerequisite for, nor a direct sign of consciousness; nevertheless, this network represents a fundamental property of brain function whose relationship to consciousness has repeatedly emerged under diverse conditions.

Although fMRI of active imagery tasks such as playing tennis has low sensitivity due to cognitive and compliance demands, its high specificity can have a profound impact on clinical decisions in specific cases. In respect to this approach, rs-fMRI of the DMN represents a more indirect assessment of consciousness, but plausibly has significantly higher sensitivity because it does not require any active cognitive capability and for this reason can be employed with all DOC patients. In patients without a clear behavioral response, in particular those deemed to be in VS/UWS, detection of residual DMN activity by rs-fMRI (which generally requires low head movement level) may prompt
more careful evaluation of the patient’s condition and of the results given by structural and metabolic imaging.

**Relationship to Structural and Metabolic Integrity**

Compared to functional measures, the role of conventional structural imaging in the diagnostic workup of DOC patients has been less thoroughly investigated. In our cohort, expert assessment of gross anatomical changes and signal abnormalities in DMN conveyed information useful for differentiating VS/UWS and MCS patients at the group level (see Supplementary Table 1). Although structural integrity of the DMN alone cannot replace functional and metabolic measures, anatomical damage could deserve more systematic consideration, as recently suggested for critically ill patients.

**FIGURE 3:** Two patients clinically diagnosed as being in vegetative state/unresponsive wakefulness state (VS/UWS), studied with resting-state functional magnetic resonance imaging, who show complete, near normal-appearing default-mode network (DMN), despite inconclusive results from other techniques. Both patients emerged from VS/UWS to minimally conscious state in the months after scanning. Although the presence of DMN does not ensure consciousness, its functional integrity may have relevant clinical implications. For both cases, the DMN was observed with independent component analysis (ICA) and seed-based analysis (SBA), performed independently for 6 seeds (precuneus extending to the posterior cingulate cortex [PCC], medial frontal cortex [MFC], and lateral parietal cortex [LPC], bilaterally). For Case 1 (disease duration = 23 months, vascular etiology, Coma Recovery Scale [CRS] score = 6), DMN activity was consistently detected for all nodes, except for the left LPC, even when this area was considered as SBA seed. For Case 2 (disease duration = 15 months, vascular etiology, CRS score = 6), the posterior DMN was apparent and this pattern was more evident with ICA than with SBA. Correlated activity was never detected in the MFC; when this area was considered as seed region, spurious non-neuronal clusters were observed. Both cases show a visible discrepancy between the significant structural damage and the apparently well-preserved DMN activity. L = left; R = right. [Color figure can be viewed in the online issue, which is available at www.annalsofneurology.org.]
patients with primary non-neurological disease.41 This is relevant because structural assessment was far less sensitive to head movement than rs-fMRI, yielding AUC = 0.72 over the entire cohort; in addition, a more detailed assessment than the “lumped” damage ranging from 0 to 4 considered here may provide even higher diagnostic accuracy. The importance of assessing structural integrity is further underlined by recent DTI results demonstrating correlation between white matter damage in DMN regions and thalamus, and the level of consciousness.42

FDG-PET yielded the best diagnostic accuracy (AUC = 0.75) and correlation with CRS-R scores (see Fig 2 and Supplementary Table 2), and is less sensitive to head movement, because it has a smoothing effect that is partially masked by the inherent blurring already present ab initio in PET images. These results agree with previous studies showing the strongest metabolic reduction in the frontoparietal cortex,2,10 and confirm that FDG-PET can robustly differentiate MCS from VS/UWS patients at the group level.11,12 Compared to the AUC = 0.87 reported in Stender et al,12 lower accuracy here is probably ascribable to differences in chosen measurement areas, lesion pattern, etiology, and uptake normalization approach. FDG-PET surpasses rs-fMRI only when all cases are included (N = 85), whereas it does not differ significantly when excluding cases most affected by movement (N = 62, see Supplementary Table 2). Compared to rs-fMRI, FDG-PET provides a global measure of brain metabolism, which is less functionally specific than assessment of residual synchronization in the DMN network. As such, the 2 techniques should be considered complementary and not competing.

Importantly, excluding the patients with largest head movement (N = 62, see Supplementary Table 2), sMRI, rs-fMRI, and PET did not differ significantly, and the performance of a multivariate model including 2 modalities was only slightly superior to that of the single modalities. Overall, there is no evidence that one technique is significantly superior to the other.

Based on behavioral observation of patients undergoing the Wada test (amobarbital injection), it has been hypothesized that functional preservation of left hemispheric function has greater impact on level of consciousness than right hemispheric function (eg, Serafetinides et al,43 Glosser et al,44 and Meador et al45). However, a large-scale study of patients with acute hemispheric stroke found no statistically significant evidence of lateralization.46 Thus, evidence for left-lateralization of the neural underpinnings of consciousness remains controversial. This issue is important also because DOC patients often have lateralized damage.47 Here, we found that differences between VS/UWS and MCS patients were stronger for the left than the right hemisphere for all 3 imaging modalities and that the integrity of the left hemisphere is predictive of better clinical status. Further confirmation of this finding is required, particularly in a cohort of patients with shorter disease duration, for whom a more univocal cause–effect relationship can be ascertained.

Two important issues not consistently investigated yet are the effects of disease duration and etiology. Most rs-fMRI studies have been conducted on patients on average in subacute phase (~6–12 months21,22,23), Our cohort had a substantially longer disease duration (25 months for VS/UWS and 40 months for MCS on average), closer to FDG-PET work (~24 months, or more12). Our data extend previous rs-fMRI data showing that a clear relationship between the integrity of DMN activity and clinical status is also found in chronic patients. This result is important because following the initial injury, multiple pathophysiological processes ensue, such as inflammation, secondary degeneration, and plastic reorganization, which may diversely impact DMN activity. We found no evidence for preferential diagnostic utility of the 3 modalities as a function of etiology; this could also be related to the small size of the subsamples, as well as to the multitude of factors associated with the long disease duration in this cohort. Anyhow, our results suggest that the distinction between SV and MCS is easier for the anoxic etiology based on both sMRI and rs-fMRI modalities, probably because anatomical damage tends to be more widespread and consistently severe for these cases, similarly impacting anatomy and function. The SV-MCS distinction is more difficult for vascular (ischemic and hemorrhagic) etiology probably because in these cases there is more nuanced and heterogeneous damage to the cortex and white matter, engendering anatomy–function dissociations and making it difficult to objectively assess damage.

**Study Limitations**
The unavailability of FDG-PET for some patients, together with the need to exclude rs-fMRI scans most severely affected by head movement, determined a split into 4 subpopulations, complicating the comparability of techniques. This limitation was addressed by choosing the best situation for each modality, and importantly the main conclusions were supported by similar results across subpopulations. Follow-up clinical data were only sparingly available, and prognostic analyses thus were not performed. We did not consider the effect of thalamic integrity, as this structure was not consistently observed.
Recent advances in rs-fMRI methodology may increase diagnostic accuracy compared to the methods used here. Multiband techniques yield longer-time series (>1,000 frames) for the same acquisition time, resulting in a drastic improvement of statistical power. Within-frame motion correction, vision-guided prospective motion correction, and multiecho imaging may significantly reduce sensitivity to head movement. Additional improvement may be attainable by including temporal derivatives, regressor temporal filtering, and cardiac and respiratory regressors.

Finally, it should be noted that not even the CRS-R scale is a gold standard quantification of the patient’s clinical condition, because scores partially overlap between different diagnoses and because it embodies the assumption that if a patient is able to show higher-level behaviors then also lower-level responses should be preserved. Future neuroimaging studies may consider revised versions of this scale that attempt to address these issues.

Conclusions
In summary, we confirm that rs-fMRI can be informative about DMN integrity in DOC patients, yielding modest but clearly significant correlation with clinical status. The viability of this technique is critically dependent on head movement, whereas sMRI and FDG-PET are much less affected. Structural integrity across DMN regions also correlates with consciousness level, and FDG-PET yields the highest accuracy scores. Multiple rs-fMRI analyses provided convergent results, and on the whole rs-fMRI does not significantly add to sMRI and FDG-PET. Nevertheless, so long as patients with the greatest head movement are excluded, there is also no evidence that either of these techniques is superior to rs-fMRI. Furthermore, all modalities provided tentative evidence that DMN integrity in the left hemisphere may be more predictive of clinical status than in the right hemisphere. In patients without a clear behavioral response, rs-fMRI could be useful in the clinical routine to complement existing diagnostic tools, to detect residual brain activity in individual cases, particularly when results from the other techniques are inconclusive.
